Abstract

Since global service providers consider seamless interworking with existing networks as the most important factor, it is most likely that LTE-Advanced of 3GPP is selected as international standard for 4G wireless communication. As such, we suggest SON based service self-organization which provides users with service continuity even when mobile users have terminal mobility and session mobility, and enable service providers to implement "heterogeneous multi-network of integrated," which guarantees better service in terms of wireless communication access, transmission speed, and Quality of Service (QoS). It is also expected to allow fast handover service such as VOD, and streaming in LTE-Advanced system. Moreover, this study could be conducted with various research institutions and manufacturers, leading joint research and technology transfer in the future.

Keywords: SON, Service Self-Organization, Service Continuity, Heterogeneous Networks

1. Introduction

For progressing to fourth-generation mobile communication, the need to evolve the systems towards supporting a wider range of telecommunication applications, involving multimedia service, is increasingly gaining importance. According to this, ITU regulates 4G technique as IMT-Advanced, and defines high data rate, network convergence, ubiquitous and seamless connection as characteristics. As a technique which satisfies above mentioned conditions, LTE-Advanced is in the spotlight now [1-3]. As shown in Figure 1, 3G LTE uses backbone based on ALL-IP, interworking with various networks seamlessly. The service offered from 3GPP LTE-Advanced is always connected with data rate of over maximum 100Mbps and minimum delay; it is possible to seamlessly interwork with existing services in WCDMA and HSDPA networks. In case of selecting 3GPP LTE-Advanced, it is possible to link existing 3G and 4G networks, so all of communication functions could be used with only one mobile terminal. The most remarkable technique for this is service continuity technique through seamless connection [4-8].

LTE-Advanced should provide high-speed data communication mainly in hot-spot area, and offer service continuity during terminal mobility and session mobility with only a mobile terminal. However, in LTE-Advanced where different networks coexist, it is actually difficult to provide service continuity efficiently [9-11]. And because each resource in LTE-Advanced system and the network state such as bandwidth, error rate change variably, it is considered

* Corresponding author: SangJoon Park
that it is impossible to control service continuity with procedural, artificial, and static control method applied to the existing voice service.

As a solution for this, we introduce a self-organizing network (SON) concept in LTE-Advanced. It is aimed at making heterogeneous networks expand more stably and efficiently through applying self-organization concept that different networks unite and interact for better effect, so that it has received a lot of attention as core technology to apply commercial system of future mobile communication networks after fourth-generation as well as LTE-Advanced [11-13]. As of yet, it mostly focuses on progress of physical aspect such as setting up base stations, performance improvement and capacity expansion, but it is thought that if a method which guarantees service continuity based on self-monitoring technique is developed, it will play a key role in market enlargement of LTE-Advanced; self-monitoring is a technology for performing traffic control and improving resource capacity by analyzing some context information about neighboring cells and terminals, which is the core technology of SON [14-15].

Figure 1. 3G LTE network structure (3GPP TS22.258)

We propose a service self-organization mechanism to support the service continuity effectively based on SON, in which a mobile terminal collects some information about its current state of each cell and a base station, based on the information collected by monitoring inner or adjacent cells, shares related data and converges, controlling service continuity on its own. In other words, as context information of mobile terminals and cells changes, the operation of related functions such as ISHO, cell selection, source allocation, load control, and QoS mapping is adapted; each function fits into the change, exchanges the process of reorganization, and interacts; these actions go toward to satisfy service continuity.

2. Previous Works

3GPP is an organization for standardizing LTE which is called 3.9th generation with GSM, WCDMA, HSDPA used by current 89% of mobile communication subscribers. It has been conducting the standardization of LTE-Advanced for satisfying the system requirement of IMT-Advanced through complement of LTE technology. Although it is hard to expect that LTE-Advanced is more progressed in epochal technology than LTE, it is supposed to be improved in the field of broadband support, multiple antenna expansion, network cooperative communication, SON technology. The study on the concept of common radio resource
management, whose objective is to manage each access network synthetically to supply ISHO function and to optimize the performance in various heterogeneous access networks, is being carried on actively. Especially, 3GPP suggests a network structure for integrated radio resources management in TR25.881 the technology standard text and common radio resource management (CRRM) the method of the integrated radio resources management to support that, and many projects to modify and complement the weak point of CRRM are being proposed.

SON is aimed to organize the network stable, efficient and scalable using the concept of self-organization. Especially, with introduction of femto cell and next generation 4G visualized in mobile communication system, SON which includes the automated functions such as self-organization or self-configuration is estimated as a key technology of commercialization. It is because SON technology, which is able to realize the simplification of management, convenience and reduction of operation and support cost, increase of capacity, and so on, is considered as an optimum alternative with reduction of total cost of ownership and improvement of managerial efficiency emerged as key words of service providers. Especially, each major equipment company also develops SON technology and devotes all their efforts to secure service providers which need to curtail the cost due to explosive increase in the amount of using data and a flat rate system. Because the sections which self-organization can be applied are really various in the mobile communication field, the concept of self-organization can be used for the individual management algorithm and the optimization technique according to the characteristics and types of network which is intended to organize in self-organization.

3. Proposed Scheme

If LTE-Advanced becomes 4G-integrated standard, and a commercialization, service providers which have various access networks, could combine a variety of access networks based on IP core network without another investment for networks. This paper, with this industrial background, suggests a layered mechanism for supporting service continuity using SON, which is core part for commercial system application in LTE-advanced heterogeneous networks. Figure 2 shows a two-layered control mechanism for the service of self-organization based on SON.

![Figure 2. Two-layered control mechanism for service self-organization](image-url)
Previously, to offer ISHO and related functions in various heterogeneous wireless networks, the researches on the integrated radio resources management which could manage each access network resource synthetically and optimize whole system operation, has been processed; there is CRRM of TRS25.88 as a representative method. However, CRRM, by focusing only on controlling sub-access networks to integration and distribution with existing RM, had a fatal defect that interworking mechanism between functions and related entities lack to support service continuity required in 4G. Especially, in LTE-Advanced which promotes the commercial service after 2015, it is obvious that convergence and interworking among functions according to use case are necessary to satisfy service requirements such as end-to-end QoS & guaranteed connection. Accordingly, the goal of this research is to propose the supporting mechanism which makes service continuity possible by enabling functions related to the state change of mobile terminal and base station to make self-control/ adaptation/ reconstruction through the suggested service self-organization.

3.1. SON based service control mechanism

The service of self-organization, which applies a SON-based control mechanism different from CRRM (TR25.881), is the overlaid control mechanism based on distributional control by two-layered structure to be supportable for both tightly coupling and loosely coupling network able to be organized according to service provider’s network configuration. As shown in Figure 3, the inner-service of self-organization (ISSO) is located in local networks to support service continuity for seamless mobility occurring between tightly coupling sub-networks in LTE-Advanced efficiently; the outer-service of self-organization (OSSO) is located in external network to manage the majority of ISSO and to support service continuity between loosely coupling sub-heterogeneous networks.

![Figure 3. Two-layered control mechanism for service self-organization](image)

Figure 4 shows the proposed control hierarchical control structure to support the service of self-organization in LTE-Advanced. All functions are located at ISSO of LTE-Advanced access network and OSSO of LTE-Advanced core network; each function is as follows; Service Management Index (SMI) rule maker which describes SMI of service providers, SMI monitor which collects the conditions applying to SMI, and SMI firer which handles functions the control system should conduct directly by Lego method.
ISSO/OSSO is designed so that both tightly and loosely coupling network can be supportable, and the service of self-organization mechanism is developed based on regional distribution and integration control of ISSO/OSSO. For this, ISSO is developed to be capable of deletion of unnecessary function and addition of function by implementing the embedded module type interconnecting with protocol.

3.2. Gearing method

To adapt to the dynamically changing environment around mobile terminals and cells, it should be capable to make self-control/adaptation/reconstruction of functions. As shown in Figure 6, the control interface based on Gearing is designed so that each function for service self-organization can be combined according to use case. After each algorithm is designed as module to be able to conduct independently in real-time processing of service continuity, information sharing and dynamic adaptation are composed for all functions to share and
adjust the information in order to exclude the confused connection in the coordination between the functions and to exclude the reason of the bottleneck. For this, the service of self-adaptation method and the service of self-monitoring method are considered. The service of self-monitoring analyzes the current state based on internal information and external information collected through monitoring mobile terminals and cells. The functions to operate in each use case are selected from the result of circumstantial judgment. The service of self-adaptation is conducted to control the related parameter automatically to be suitable for conditions. Each function with operation mechanisms interacts, reciprocating the process to reconstruct and adjust to changes.

![Service self-organization mechanism based on Gearing method](image)

**Figure 6. Service self-organization mechanism based on Gearing method**

The procedure which the service of self-organization is adapted is as following. All containers for monitoring in networks collect reporting information such as SLA information, accessible cell information of each mobile terminal, and QoS of mobile terminals; Monitor is periodically implemented by the Condition of Firing SMI (CFS). If one condition of the CFS is satisfied, Conditioner sends a message to SMI Ruler for ruling. SMI Rule maker decides what function to conduct through already established SMI, and delivers Firing message including SMI information to related Firer, which could operate suitably for SMI through it. Each functional algorism getting firing messages conducts actions for SMI decision and sends the result to Sub-Firer. Each rule is located separately in ISSO and OSSO according to its role. These procedures can be conducted in the process of service operation, and adapted on the way of transmission of traffic after completion of service operation.

### 3.3. Lego method

In order to effectively implement the service of self-organization and commercialize it, coping adaptively with the management direction of each service providers, Lego based function combination is considered. Through this, open interface, modularity, flexibility, commonality can be satisfied at the same time. This applies the modularization scheme used in mechanical engineering, and is an epochal lego-style treating method which enables
adaptive combination and separation of different functions by stratifying and dichotomizing interface with lego-style adapted between the functions. Figure 7 shows an example of the combinable function according to use case. For example, despite the new session requirement, functions to use are selected by conditions of firing SMI and monitoring some information such as user, terminal, near base station, and radio condition. The optimum result in current condition can be obtained by making different parameters between the shared functions.

Figure 7. Examples of the combinable functions by Lego method

Lego based function combination is designed for acting in each parameter appropriate for service area where mobile terminals are located, by deciding action of each function and optimizing separately only with local information according to distributed processing concept of the service of self-organization. For this, Lego based function combination needs three element technologies from the technical point of view. Those three element technologies are as follows; dynamically interconnecting scheduler which combines functions according to use case putting lego based function combination to use; interconnecting structure by function which extracts composition elements of each function, i.e. terminal elements, system elements including base station, wireless network element, and formulates their correlation according to use case; interconnecting structure by parameter for efficient adaptation of related parameter according to environmental change; task-based design for optimizing operation as well as minimizing behavior process. Figure 8 shows interconnecting structure for allocation of shared value during cell selection, in case of terminal mobility.

4. Conclusion
The proposed service scheme of self-organization is very important factor that could affect the performance of the integrated system. Also IPR is also expected to become important. Initial success of LTE-Advanced related technology developed based on this scheme would give us an advantageous position for developing other related technologies - standardizing them, and preempting emerging technology. Accordingly, we would be able to respond promptly to the trend in international research and patent application by collecting all the related technologies required for the service continuity in LTE-Advanced system and establishing source technology based on them.
